ABSTRACT

Context. Since its launch, the *Fermi* satellite has firmly identified 5 pulsar wind nebulae plus a large number of candidates, all powered by young and energetic pulsars. HESS J1857+026 is a spatially extended γ -ray source detected by H.E.S.S. and classified as a possible pulsar wind nebula candidate powered by PSR J1856+0245.

Aims. We search for γ -ray pulsations from PSR J1856+0245 and explore the characteristics of its associated pulsar wind nebula.

Methods. Using a rotational ephemeris obtained from the Lovell telescope at Jodrell Bank Observatory at 1.5 GHz, we phase-fold 36 months of γ -ray data acquired by the Large Area Telescope (LAT) aboard *Fermi*. We also perform a complete γ -ray spectral and morphological analysis.

Results. No pulsation was detected from PSR J1856+0245. However, significant emission is detected at a position coincident with the TeV source HESS J1857+026. The γ -ray spectrum is well described by a simple power law with a spectral index of $\Gamma = 1.53 \pm 0.11_{\text{stat}} \pm 0.55_{\text{syst}}$ and an energy flux of $G(0.1\text{--}100 \text{ GeV}) = (2.71 \pm 0.52_{\text{stat}} \pm 1.51_{\text{syst}}) \times 10^{-11} \text{ ergs cm}^{-2} \text{ s}^{-1}$. This implies a γ -ray efficiency of $\sim 5\%$, assuming a distance of 9 kpc, the γ -ray luminosity of $L_{\text{PWN}}^{\gamma}(0.1\text{--}100 \text{ GeV}) = (2.5 \pm 0.5_{\text{stat}} \pm 1.5_{\text{syst}}) \times 10^{35} \left(\frac{d}{9 \text{ kpc}}\right)^2 \text{ ergs s}^{-1}$ and $\dot{E} = 4.6 \times 10^{36} \text{ erg s}^{-1}$, in the range expected for pulsar wind nebulae. Detailed multi-wavelength modeling provides new constraints on its pulsar wind nebula nature.

Key words. pulsars : general, pulsars : individual object : PSR J1856+0245, ISM : individual object : HESS J1857+026, Gamma rays : general

1. Introduction

Pulsar wind nebulae (PWNe) are bubbles of shocked relativistic particles produced by the interaction of the pulsar's wind with the surrounding medium (Gaensler et al. 2006). Since 2003, the continuous observations of the Galactic Plane by Čerenkov telescopes have yielded the detection of more than 60 Galactic TeV sources. Among them, PWNe are the dominant class with 29 firm identifications. In the GeV energy range, 5 PWNe have been firmly identified by the *Fermi*-LAT. They are all powered by en-

ergetic pulsars and their γ -efficiencies are $\sim 1\%$, consistent with TeV observations (Ackermann et al. 2011).

The presence of a pulsar close to the source position is an important clue to confirm the identification of a PWN, which often requires information from the radio/X-ray wavelengths. Radio/X-ray PWNe are often associated with TeV extended sources offset from their pulsars, which can be explained by an inhomogeneous environment (Hinton et al. 2010). In such sources, TeV radiation can be explained by Inverse Compton (IC) scattering of accelerated leptons on ambient photon fields

(CMB, IR, ...) or by π^0 decay from the interaction of accelerated hadrons with nuclei of the interstellar medium.

HESS J1857+026 is a very high energy (VHE) γ -ray source detected by H.E.S.S. during the Galactic Plane Survey (Aharonian et al. 2008). The extended ($\sim 0.11^\circ$) TeV source was identified as a PWN candidate after the discovery of PSR J1856+0245 (offset $\sim 0.12^\circ$) in the Arecibo PALFA survey (Hessels et al. 2008) with a dispersion measure of 222 cm^{-3} pc. Recently, MAGIC reported a measured extension in the 0.2–1 TeV energy range significantly larger (0.22°) than the extension reported by H.E.S.S. in the 0.6–80 TeV energy range (Klepser et al. 2011). PSR J1856+0245 is an energetic pulsar ($\dot{E} = 4.6 \times 10^{36} \text{ erg s}^{-1}$) located in a crowded region, 1.3° from the bright SNR W44 (Abdo et al. 2010) and 0.6° from the fainter SNR HESS J1858+020 on which only an upper limit could be set using *Fermi* data (Torres et al. 2011). Significant emission coincident with HESS J1857+026 was observed above 100 GeV using *Fermi*-LAT observations (Neronov et al. 2010).

Here, we report in detail GeV observations of the HESS J1857+026/PSR J1856+0245 system using *Fermi*-LAT observations and discuss their implications for the nature of the source.

2. LAT description and data selection

The LAT is a γ -ray telescope that detects photons by conversion into electron-positron pairs and operates in the energy range between 20 MeV and 300 GeV. Details of the instrument and data processing are given in Atwood et al. (2009). The on-orbit calibration is described in Abdo et al. (2009a).

The following analysis was performed using 36 months of data collected from August 4, 2008 to August 31, 2011 within a $10 \times 10^\circ$ square around the position of HESS J1857+026 aligned with Galactic coordinates. We excluded γ -rays coming from a zenith angle larger than 100° because of possible contamination from secondary γ -rays from the Earth's atmosphere (Abdo et al. 2009b). We used the P7 V6 Instrument Response Functions (IRFs), and selected the ‘Source’ events which correspond to the best compromise between the number of selected photons and the charged particle residual background for the study of point-like or slightly extended sources.

3. Data analysis

3.1. Timing analysis of PSR J1856+0245

With its large spin-down power, PSR J1856+0245 is one of the more energetic radio pulsars known. Its spin period of 80.9 ms and characteristic age of 20.6 kyr are similar to those of the Vela pulsar. The dispersion measure and NE2001 electron density model of the Galaxy assign PSR J1856+0245 a distance of $\sim 9 \text{ kpc}$ (Cordes et al. 2002).

This pulsar is not monitored as part of the LAT pulsar timing campaign (Smith et al. 2008), as it was discovered subsequently, but has nevertheless been regularly observed with the Lovell telescope at Jodrell Bank Observatory (Hobbs et al. 2004). The ephemeris of PSR J1856+0245 used in the analysis was obtained using 82 observations at **1.5 GHz** made with the Lovell telescope between May 4, 2008 and September 4, 2011. The arrival times of events were corrected to the Solar System Barycenter using the JPL DE405 Solar System ephemeris. The TEMPO2 timing package (Hobbs et al. 2006) was then used to build the timing solution. We fit the radio times of arrival (TOAs) to the pulsar rotation frequency and first four derivatives (in order to remove timing noise). By including a fourth derivative the RMS of the

Parameter	Value

timing residuals decreases in about 30%. It goes from 1.551 ms to 1.081 ms, which is equivalent to a decrease from 19 to 13 milliperiods. The reduced χ^2 of the fit also decreases significantly, changing from 22 to 5. **The fit results are summarized in Table 1.**

This timing solution will be made available through the *Fermi* Science Support Center¹ (FSSC).

For the LAT analysis, photons with energies above 100 MeV and within a radius of 1.0° of the radio pulsar position $\alpha(\text{J2000}) = 18^h56^m50.937^s$, $\delta(\text{J2000}) = +02^\circ45'47.046''$ were selected using an energy-dependent cone of radius $\theta < \max(5.12^\circ \times (E/100 \text{ MeV})^{-0.8}, 0.2^\circ)$ and phase-folded using the radio ephemeris previously described. This choice takes into account the instrument performance and improves the signal to noise ratio over a broad energy range. No significant pulsation was detected for all tested energy bands (100 MeV – 300 GeV, 100 MeV – 300 MeV, 300 MeV – 1 GeV, $> 1 \text{ GeV}$). Following the procedure used by Romani et al. (2011), we fitted a point source at the position of PSR J1856+0245 in the 0.1 – 1 GeV energy range assuming a power-law of index 1.62 and a cut-off energy at 2.8 GeV to derive a 99% Bayesian upper limit on the flux of $3.27 \times 10^{-8} \text{ ph cm}^{-2} \text{ s}^{-1}$, well below typical γ -ray fluxes reported for pulsars detected by *Fermi*-LAT (Abdo et al. 2010c).

3.2. Spatial and spectral analysis

Two different tools were used to perform the spatial and spectral analysis: *gtlike* and *pointlike*. *gtlike* is a binned maximum-likelihood method (Mattox et al. 1996) implemented in the Science Tools distributed by the FSSC. *pointlike* is an alternate binned likelihood technique, optimized for characterizing the extension of a source (unlike *gtlike*), that was extensively tested against *gtlike* (Kerr 2011). These tools fit a source model to the data along with models for the instrumental, extragalactic and Galactic components of the background. In the following analysis, the Galactic diffuse emission is modeled by the standard LAT diffuse emission ring-hybrid model *gal_2yearp7v6_v0.fits*. The residual cosmic-ray background and extragalactic radiation are described by a single isotropic component with a spectral shape described by the file *iso_p7v6source.txt*. The models have been released and described by the *Fermi*-LAT Collaboration through the FSSC².

¹ FSSC: <http://fermi.gsfc.nasa.gov/ssc/data/access/lat/ephems/>

² <http://fermi.gsfc.nasa.gov/ssc/data/access/lat/BackgroundModels.html>

The source significance is measured by a test statistic (TS) defined as $TS = 2(\log(L_1) - \log(L_0))$, where L_1 corresponds to the likelihood obtained by fitting a model of the source of interest and the background model and L_0 corresponds to the likelihood obtained by fitting the background model only. In the following, the correspondence between the significance and the TS value is evaluated from the χ^2 distribution with 4 degrees of freedom (position and spectral parameters).

The 41 sources within 15° of HESS J1857+026 in the Second *Fermi*-LAT catalog (Abdo et al. 2011) were taken into account. We refitted all spectral parameters of the 16 sources within 5° around HESS J1857+026. The region includes the bright SNR W44, known to interact with its environment. Extended and only 1.3° from HESS J1857+026, W44 could influence our fit. We refitted it assuming an elliptical ring and obtained results consistent with those of Abdo et al. (2010a). The centroid is located at $\alpha = 18^h56^m$, $\delta = +01^\circ22'$. The fitted semi major and semi minor axes are respectively $\text{maj}/2 = (0.33 \pm 0.10_{\text{stat}})^\circ$, $\text{min}/2 = (0.20 \pm 0.02_{\text{stat}})^\circ$. The angle of the semi major axis from celestial North, considered positive toward increasing right ascension, is $(327 \pm 22_{\text{stat}})^\circ$.

3.2.1. Shape and position of HESS J1857+026 counterpart

Source shape analysis requires the best possible angular resolution. Since the source has a hard spectrum (see Section 3.2.2) we made a compromise between statistics and resolution by selecting photons above 10 GeV. This drastically reduces the contribution of the Galactic diffuse background and improve the single-photon angular resolution. Fig. 1 (Top) presents a LAT TS Map in the energy range of 10 GeV to 300 GeV. To each pixel is associated a TS value calculated assuming a point source in its center and fitting only the flux of the source assuming a power law spectrum with a spectral index of 2. A source coincident with HESS J1857+026 is clearly visible. We determined the extension of the source using *pointlike* with three different models : a point source, a uniform disk and a Gaussian. No significant extension was obtained above 10 GeV. The GeV emission was fit to position $\alpha(J2000) = 18^h57^m$, $\delta(J2000) = +02^\circ45'$ with an average statistical error of 0.05° , consistent with the position determined by H.E.S.S. $\alpha(J2000) = 18^h56^m50.80^s$, $\delta(J2000) = +02^\circ45'50.2''$.

3.2.2. Spectral analysis

Fig. 1 (Middle) shows a TS map of the region in the energy range 0.1–1.3 GeV. There is excess emission near HESS J1857+026 located at $\alpha(J2000) = 18^h54^m$, $\delta(J2000) = +02^\circ59'$. This excess is inconsistent with that of HESS J1857+026 and was added to the background model. This additional background source was fitted assuming a pure power-law with an integrated flux of $F(0.1\text{--}100 \text{ GeV}) = (2.31 \pm 0.37_{\text{stat}}) \times 10^{-7} \text{ ph cm}^{-2} \text{ s}^{-1}$, a spectral index of $\Gamma = 3.18 \pm 0.56_{\text{stat}}$, which gives a significance above 300 MeV of $\sim 3.6\sigma$ (TS=20).

Spectral analysis was performed using *gtlike*, selecting only 0.3–300 GeV to avoid the low energy range that is dominated by the diffuse Galactic background and subject to high systematics. In this energy range, HESS J1857+026 is well described by a pure power-law with an integrated flux extrapolated down to 100 MeV of $F(0.1\text{--}100 \text{ GeV}) = (5.78 \pm 0.85_{\text{stat}} \pm 3.11_{\text{syst}}) \times 10^{-9} \text{ ph cm}^{-2} \text{ s}^{-1}$, a spectral index of $\Gamma = 1.53 \pm 0.11_{\text{stat}} \pm 0.55_{\text{syst}}$ and an energy flux of $G(0.1\text{--}100 \text{ GeV}) = (2.71 \pm 0.52_{\text{stat}} \pm 1.51_{\text{syst}}) \times 10^{-11} \text{ ergs cm}^{-2} \text{ s}^{-1}$, which gives a signifi-

cance above 300 MeV of $\sim 5.4\sigma$ (TS=39). The residual TS map after fit is presented in Fig.1 (Bottom) and shows no significant excess.

Fermi-LAT spectral points for HESS J1857+026 were obtained by splitting the 0.3–100 GeV range into 4 logarithmically-spaced energy bins plus a bin between 100 and 300 GeV which contains 22 photons corresponding to a TS of 14, as presented in Fig. 2. A 99 % C.L. upper limit is computed when $TS < 10$ using the approach used by Abdo et al. (2011). The errors on the spectral points represent the statistical and systematic uncertainties added in quadrature.

Three main systematic uncertainties can affect the LAT flux estimate for a point source: uncertainties in the Galactic diffuse background, uncertainties on the effective area and uncertainties on the shape of the source. The dominant uncertainty at low energy comes from the Galactic diffuse emission, estimated by changing the normalization of the Galactic diffuse model artificially by $\pm 6\%$ as done in (Abdo 2010 b). Since it is computed for P6 IRFs, the 6% factor overestimates the bias. The second systematic is estimated by using modified IRFs. The fact that we do not know the true γ -ray morphology introduces a last source of error. We derived an estimate of the uncertainty on the shape of the source by using the best Gaussian model obtained by HESS. We combine this various errors in quadrature to obtain our best estimate of the total systematic error at each energy and propagate through to the fit model parameters.

Assuming a distance of 9 kpc and an isotropic emission, the γ -ray flux corresponds to $L_{\text{PWN}}^\gamma(0.1\text{--}100 \text{ GeV}) = (2.5 \pm 0.5_{\text{stat}} \pm 1.5_{\text{syst}}) \times 10^{35} \left(\frac{d}{9 \text{ kpc}}\right)^2 \text{ ergs s}^{-1}$. Using the pulsar's \dot{E} , this yields a γ -ray efficiency of $\sim 5\%$, which is one of the highest PWN efficiencies observed at GeV energies (Ackermann et al. 2011). It is still in the range of expected values for PWNe seen by Fermi and is close to the estimate of 3% using HESS data (Mattana et al. 2009).

4. Supporting X-Ray measurement

To obtain a precise flux for any potential X-ray PWN associated with PSR J1856+0245, we analyzed a 39-ks *Chandra* ACIS-I observation from February 28, 2011 (Obs. ID 12557). These data were recorded in the VFAINT and Timed Exposure (TE) modes and were analyzed using CIAO³ version 4.3.1 with CALDB 4.4.3. PSR J1856+0245 is clearly detected as a point source, but there was no immediate evidence for extended emission surrounding this position. **In the 2–10 keV energy range, assuming a power law spectrum to fit the XMM data, the unabsorbed flux of the pulsar is $8.3^{+2.5}_{-7.9} \times 10^{-14} \text{ erg s}^{-1}$.** An in-depth analysis of the X-ray properties of PSR J1856+0245 as well as the XMM data will be presented in Bogdanov et al. (in preparation).

Given that the size of the potential X-ray PWN is not known, we investigated an extraction region to see whether they produce a statistically significant excess of counts compared with the background. This extraction region is in the form of annuli extending from $2''$ – $15''$ from the position of the pulsar. **The inner radius was chosen to avoid contamination from the pulsar. The outer radius was chosen based on the X-Ray PWNe observed for pulsars with comparable \dot{E} by scaling their angular size with their distance (Kargaltsev & Pavlov 2008).** The background regions were chosen from several other source-

³ Chandra Interactive Analysis of Observations (Fruscione et al. 2006).

free regions in the vicinity of the pulsar. For the $2'' - 15''$ extraction region we find an upper limit on the unabsorbed flux of $5 \times 10^{-14} \text{ erg s}^{-1} \text{ cm}^{-2}$ (1–10 keV, 3σ confidence), corresponding to a luminosity of $5 \times 10^{32} \text{ erg s}^{-1}$. The counts in this region show a 2σ excess from zero counts. Assuming now the TeV position and a $6'$ extraction region consistent with the HESS morphology, we find an upper limit on the unabsorbed flux of $2 \times 10^{-12} \text{ erg s}^{-1} \text{ cm}^{-2}$ (1–10 keV, 3σ confidence), corresponding to a luminosity of $2 \times 10^{34} \text{ erg s}^{-1}$. Given the marginal significance of the count excesses derived, we cannot convincingly claim the detection of a weak X-ray PWN. These luminosity limits are derived from the 3σ upper bound on the net count rate and assume a typical power-law spectrum of index 1.5 for the PWN, a distance of 9 kpc, and a column density $N_H = 4 \times 10^{22} \text{ cm}^{-2}$ based on the spectroscopic analysis of the XMM data.

5. Discussion

To investigate the global properties of the putative PWN, we apply a one-zone time dependent Spectral Energy Distribution model which reproduces the multi-wavelength measurements from MAGIC (Klepser et al. 2011), H.E.S.S. (Aharonian et al. 2008), as well as the LAT and the $6'$ X-ray upper limit described above, consistent with the TeV morphology.

This model, described in Grondin et al. (2011), computes SEDs from evolving electron populations over the lifetime of the pulsar in a series of time steps. During the free-expansion phase of the PWN (assumed to be $\sim 10^4$ years) we adopt an expansion of $R \propto t$, following which the radius evolves as $R \propto t^{0.3}$, appropriate for a PWN expanding in pressure equilibrium with a Sedov phase SNR. **While the transition from free expansion to the Sedov phase may be accompanied by a PWN compression, this compression depends on a number of parameters which are unconstrained here (ISM density, supernova ejecta mass, ...). Therefore, for simplicity, we assumed a smooth transition at 10^4 years.** Over the pulsar lifetime the magnetic field evolves as $B \propto t^{-1.5}$, as explained in Van Etten & Romani (2011), following ~ 500 years of constancy. At each time step synchrotron, IC (Klein-Nishina effects included), and adiabatic losses are calculated. Synchrotron and IC fluxes are calculated from the final electron spectrum.

Using our ephemeris, we tried to derive a value for the braking index using eq. 1 where ν , $\nu^{(i)}$ and n represents respectively the rotational frequency of the pulsar, its time derivative of order i and the braking index.

$$n = \frac{\nu \nu^{(2)}}{(\nu^{(1)})^2} \quad (1)$$

We obtained $n > 20$. Large braking indices between glitches are common among Vela-like pulsars and are likely to be associated with glitch recoveries. These large values should not be interpreted as the long-term braking index due to secular spin evolution **but instead** these correspond to transient states caused by large glitch activity as discussed in section 3.2.2 of Hobbs et al. (2010). **Dipole braking indices have been measured only for a few pulsars with the highest spindown rates (see Table 1 of Espinoza et al. (2011)).**

With its ~ 21 kyr of characteristic age, PSR J1856+0245 is a Vela-like pulsar possibly affected by quite a large glitch activity, which we have not yet directly seen. Thus, we fix here the pulsar braking index to the canonical value of 3.

We assume the existence of three primary photon fields (CMBR, far IR (dust), and starlight) and use the interstellar ra-

diation field from GALPROP (Porter et al. 2005) to estimate the photon fields at the Galactic radius of PSR J1856+0245. A distance of 9 kpc in the direction of the pulsar corresponds to a Galactic radius of 5.4 kpc. At this radius, the peak of the SED of dust IR photons corresponds to a black body temperature of $T \sim 32$ K with a density of $\sim 1.1 \text{ eV cm}^{-3}$, while the SED of stellar photons peaks at $T \sim 2500$ K with a density of $\sim 1.2 \text{ eV cm}^{-3}$.

For PWNe with radio data a broken power-law injection of electrons, evolved properly over the pulsar lifetime, often provides an adequate match to PWN SEDs (Tanaka & Takahara 2011). In the absence of constraining radio data for HESS J1857+026, we adopt a somewhat simpler injection spectrum consisting of a power-law with a high energy exponential cutoff. For this injection spectrum we fit four variables: final magnetic field $B_f = 3.7 \pm 0.5 \mu\text{G}$, electron high energy cutoff $E_{\text{cut}} = 99 \pm 37$ TeV, electron power-law index $p = 2.08 \pm 0.03$, and initial pulsar spin period $P_0 = 9.6 \pm 6.1$ ms, which gives an age of 20 ± 1 kyr. This model yields a $\chi^2/dof = 24.9/21$ and poorly matches the low energy MAGIC points, as shown in Figure 2 (Top). **The low value of the magnetic field is still reasonable in Sedov phase if one ignores possible compression from the reverse shock.**

Another option to fit the multi-wavelength data is to adopt the relativistic Maxwellian plus power-law tail electron spectrum proposed by Spitkovsky (2008) as done in Slane et al. (2010). We implement this spectrum as described in Grondin et al. (2011). The best fit, presented in Fig. 2 (Middle), is obtained with $kT = 0.64 \pm 0.09$ TeV corresponding to an upstream Lorentz factor of 2.5×10^6 , a magnetic field of $B_f = 2.6 \pm 0.7 \mu\text{G}$, a cutoff at $E_{\text{cut}} = 450 \pm 290$ TeV and a power-law index of $p = 2.49 \pm 0.09$, consistent with the value of ~ 2.5 proposed by Spitkovsky (2008). The braking index of $n = 3$ and initial spin period of $P_0 = 36 \pm 4$ ms give an age of 13 ± 1 kyr. The relativistic Maxwellian plus power law model better matches the multi-wavelength data, with a $\chi^2/dof = 12.4/20$, and also directly probes the upstream pulsar wind via fitting of γ_0 .

A hadronic scenario is also possible, with γ -rays arising from proton-proton interactions. For this model, corresponding to Fig. 2 (bottom), we fix the ambient gas density at 50 cm^{-3} and age at 20 kyr. We find a best fit of $\chi^2/dof = 24.6/21$ with a magnetic field of $B_f = 20^{+80}_{-20} \mu\text{G}$, proton cutoff at $E_{\text{p,cut}} = 75 \pm 25$ TeV, a proton power-law index of $p = 1.83 \pm 0.04$, and an energy content in protons of $(6.4 \pm 0.6) \times 10^{49} \text{ erg}$.

6. Conclusions

Using 3 years of *Fermi*-LAT data, a γ -ray source has been detected at high significance at a position coincident with the PWN candidate HESS J1857+026. This VHE spectrum observed by MAGIC and H.E.S.S., combined with the limits imposed by the steep LAT data, is difficult to match with a simple power-law injection of electrons (or protons), and we find a significantly better fit with a relativistic Maxwellian plus power-law spectrum. The low magnetic field of the leptonic fits, due to the stringent X-ray upper limit, implies that if PWN leptons are indeed responsible for the γ -ray flux, they must be dominated by relic electrons which have escaped the PWN core into weakly magnetized surroundings. The hadronic scenario relaxes this constraint, though the energy requirements are quite high even for a dense ambient medium, and a very hard power-law index is required. At present the true nature of HESS J1857+026 remains a mystery, though the new LAT data and X-ray upper limit hint that this

³ <http://galprop.stanford.edu/resources.php?option=data>

source may be another relic PWN, increasing the population of such high energy γ -ray systems.

Acknowledgements The *Fermi*-LAT Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Energie Atomique and the Centre National de la Recherche Scientifique / Institut National de Physique Nucléaire et de Physique des Particules in France, the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden.

Additional support for science analysis during the operations phase is gratefully acknowledged from the Istituto Nazionale di Astrofisica in Italy and the Centre National d’Études Spatiales in France.

The Lovell Telescope is owned and operated by the University of Manchester as part of the Jodrell Bank Centre for Astrophysics with support from the Science and Technology Facilities Council of the United Kingdom.

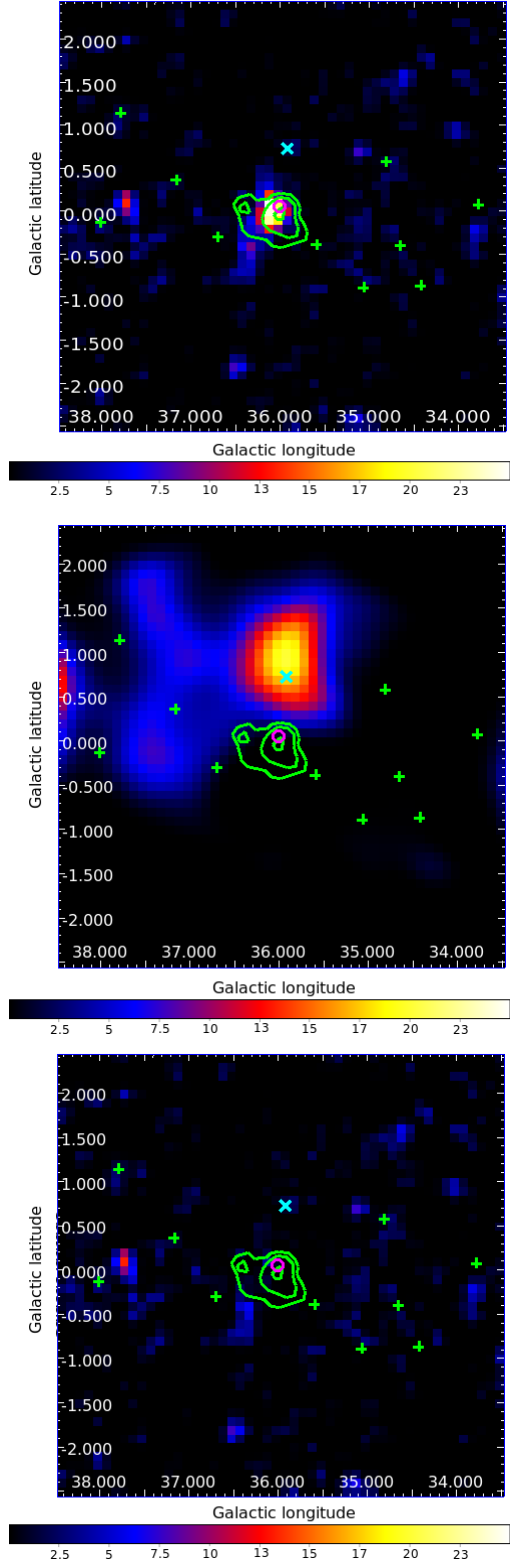

Fig. 1. TS maps computed by pointlike. The green crosses represent the sources of the 2FGL catalog included in the model, whereas the blue X represents the source we added in the model. The green contours represent the H.E.S.S. data (Aharonian et al., 2008). The magenta circle represents the position of PSR J1856+0245. **Top:** TS map obtained between 10 and 300 GeV. The position of the *Fermi* excess is consistent with that of H.E.S.S. Note that HESS J1857+026 is not included in the model. **Middle:** TS map obtained between 0.1 and 1.3 GeV. This figure shows the residual excess taken into account in our model. **Bottom:** Residual TS map obtained between 10 and 300 GeV when all the sources are taken into account.

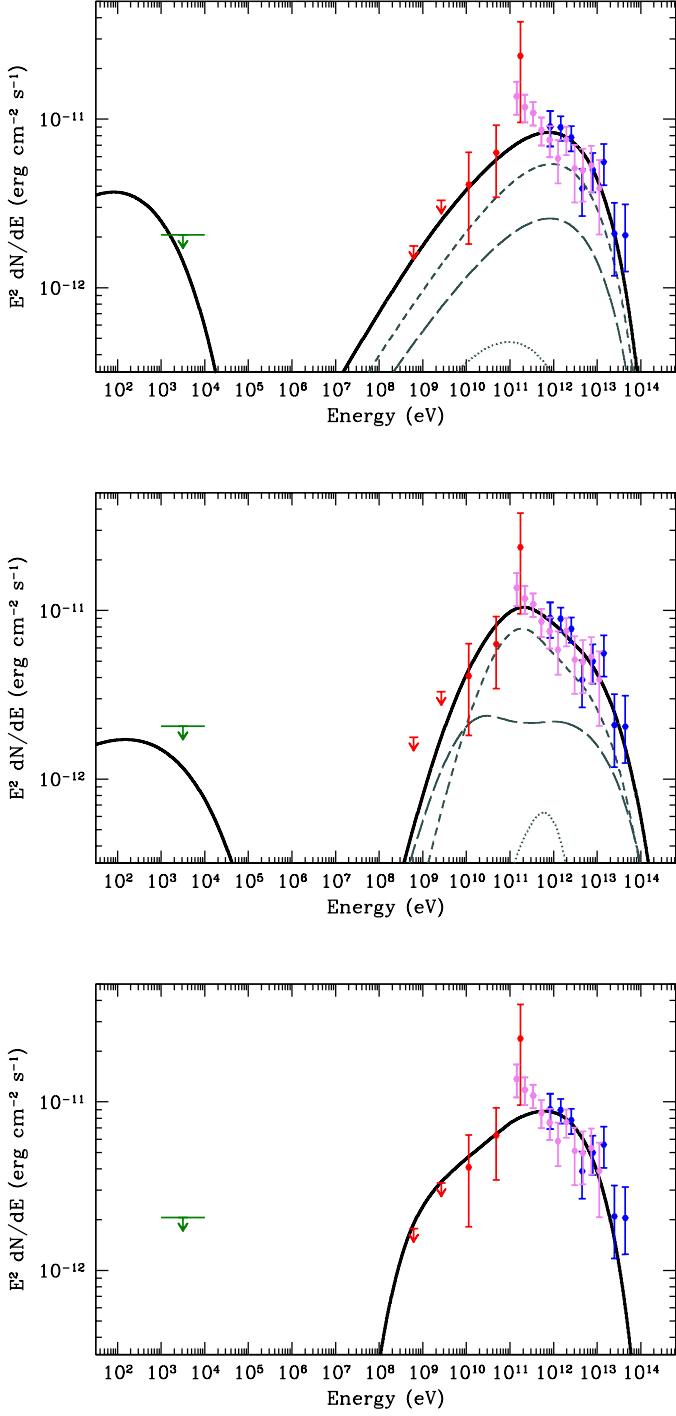

Fig. 2. Spectral energy distribution of HESS J1857+026 with a simple exponentially cutoff power-law electron spectrum (**Top**), a relativistic Maxwellian plus power-law electron spectrum (**Middle**), and an exponentially cutoff power-law proton spectrum (**Bottom**). The X-ray flux upper limit obtained using Chandra (green), LAT spectral points (red), MAGIC points (violet) (Klepser et al. 2011), and H.E.S.S. points (blue) (Aharonian et al. 2008) are shown. The black line denotes the total synchrotron, inverse Compton and pion decay emission from the nebula. Thin curves indicate the Compton components from scattering on the CMB (long-dashed), IR (medium-dashed), and stellar (dotted) photons.
